

STATISTICS FOR CLINICAL TRIALS

Applications using R

Christophe Lalanne

dda616b

Foreword

Statistical analysis were done using R version 3.6.1 (2019-07-05), which is freely available from CRAN. You may find convenient to run R through RStudio. Indeed, RStudio offers really great support for editing and running R scripts. You can even organize your work into a project, with version control and automatic reporting built on the fly. I personally choose to work with a simple text editor and an interactive shell available within few key presses. This is possible thanks to Emacs and the brilliant ESS mode.

I no longer hold a personal licence for SAS (although I could probably get an academic one) but you can try to replicate SAS results using SAS University Edition. It can run locally on your computer using Virtual Box). In addition, I provide Stata code to replicate most if not all analyses described in this document. The code has been tested with Stata 13 but should work on any version > 10.

1 Analysis of Clinical Trials using SAS

The following analyses are based on Dmitrienko et al. [2005], with data available online at Analysis of Clinical Trials Using SAS: A Practical Guide.

1.1 The HAMD17 study

Context. This is a multi-center clinical trial comparing experimental drug vs. placebo in patients with major depression disorder. The outcome is the change from baseline after 9 weeks of acute treatment, and efficacy is measured using the total score of the Hamilton depression rating scale (17 items).

This is a classical application of unbalanced design and potential heterogeneity between clinical centres, where there is an unequal number of observations per treatment (here, drug by center).

Here is one of many ways to get data right into R:

```
raw <- textConnection("
100 P 18 100 P 14 100 D 23 100 D 18 100 P 10 100 P 17 100 D 18 100 D 22
100 P 13 100 P 12 100 D 28 100 D 21 100 P 11 100 P 6 100 D 11 100 D 25
100 P 7 100 P 10 100 D 29 100 P 12 100 P 12 100 P 10 100 D 18 100 D 14
101 P 18 101 P 15 101 D 12 101 D 17 101 P 17 101 P 13 101 D 14 101 D 7
101 P 18 101 P 19 101 D 11 101 D 9 101 P 12 101 D 11 102 P 18 102 P 15
102 P 12 102 P 18 102 D 20 102 D 18 102 P 14 102 P 12 102 D 23 102 D 19
102 P 11 102 P 10 102 D 22 102 D 22 102 P 19 102 P 13 102 D 18 102 D 24
102 P 13 102 P 6 102 D 18 102 D 26 102 P 11 102 P 16 102 D 16 102 D 17
102 D 7 102 D 19 102 D 23 102 D 12 103 P 16 103 P 11 103 D 11 103 D 25
103 P 8 103 P 15 103 D 28 103 D 22 103 P 16 103 P 17 103 D 23 103 D 18
103 P 11 103 P -2 103 D 15 103 D 28 103 P 19 103 P 21 103 D 17 104 D 13
104 P 12 104 P 6 104 D 19 104 D 23 104 P 11 104 P 20 104 D 21 104 D 25
104 P 9 104 P 4 104 D 25 104 D 19
")
d <- scan(raw, what = "character")
rm(raw)
d <- as.data.frame(matrix(d, ncol = 3, byrow = TRUE))
names(d) <- c("center", "drug", "change")
d$change <- as.numeric(as.character(d$change))
d$drug <- relevel(d$drug, ref = "P")
```

Briefly, the idea is to copy and paste the SAS DATALINES instructions provided in the textbook as raw text and to scan the flow of characters. This works quite well when there is not too much data. Otherwise, it is better to store the data in text file and read it in R directly. The next bit of code uses matrix to arrange the data into a tabular dataset with 3 columns corresponding to center, drug and change score. When transforming this table to a data frame, center and drug will be converted to factors but we need to handle the proper conversion of change to numerical values. Also, note that we set the reference category to the Placebo group to simplify things a bit.

Some basic exploratory graphical analysis follows. In the next chunk, we display the raw data for each centre and highlight the difference between drug and placebo using a trend line (Figure 1). Note the use of `aes(group = 1)` when calling `geom_smooth` as there is no real grouping variable in the data structure other than the ones that are already used (drug on the x-axis and center for facetting).

```
p <- ggplot(data = d, aes(x = drug, y = change)) +
  geom_jitter(width = .2, color = grey(.3)) +
  geom_smooth(aes(group = 1), method = "lm", se = FALSE, colour = "lightcoral") +
  facet_grid(~ center) +
  labs(x = "Drug type", y = "HAMD17 change")
p
```

Figure 1: Distribution of change scores in each centre

Using the `Hmisc` package, we can easily build a Table of summary statistics by drug and center. For simplicity, the display is limited to the first 3 centers in Table 1. Note that some of the formatting options are handled directly in the `print` or `latex` function, which is masked in the following code chunk.

```
fm <- change ~ drug + center
s <- summary(fm, data = subset(d, center %in% c("100", "101", "102")),
             method = "cross", fun = smean.sd)
```

Table 1: Mean HAMD17 change by drug, center

drug	100			101			102			Total		
	N	Mean	SD	N	Mean	SD	N	Mean	SD	N	Mean	SD
P	13	12	3.4	7	16	2.7	14	13	3.6	34	13	3.6
D	11	21	5.6	7	12	3.3	16	19	4.7	34	18	5.7
Total	24	16	6.3	14	14	3.7	30	16	5.0	68	16	5.3

Only 3 out of 5 centres are shown.

Let us consider the average change scores by center, which are displayed in Figure 2. First, we need to compute the average score in each group, and then compute the difference between the two (delta). This could be done with `Hmisc` `summarize` command, but we will rely on the `plyr` package and its `ddply` command. What is important is that the results are returned as a data frame to facilitate the use of `ggplot` data structure in turn.

```
m <- with(d, summarize(change, llist(drug, center), mean))
r <- aggregate(change ~ center, m, diff)
p <- ggplot(data = r, aes(x = center, y = change)) +
  geom_point() +
  geom_hline(yintercept = 0, linetype = 2, colour = grey(.3)) +
  labs(x = "Center", y = "Difference D-P")
p
```

Now comes the modeling stage. First, we will analyse the primary endpoint using fixed-effect models. Dmitrienko et al. [2005] provide all the maths that are necessary to understand how to

Figure 2: Average difference between drug and placebo in each centre

derive various types of sum of squares, and this is further addressed in, e.g., [Christensen, 2002]. Let us first update the formula we used for producing Table 1 to allow for an interaction term between drug and center, which is denoted as `drug:center` in R. Of note, in R, `drug * center` will expand to `drug + center + drug:center`:

```
fm <- change ~ drug * center
replications(change ~ drug:center, data = d)

## $`drug:center`
##      center
## drug 100 101 102 103 104
##   P   13   7  14  10   6
##   D   11   7  16   9   7
```

As can be seen, data are slightly imbalanced for all but centre 101.

By default, R computes so-called “sequential” Type I sum of squares (SS), and here is what we get when using a standard combination of `lm` (to compute parameter estimates) and `anova` (to build the ANOVA table for the regression model):

```
options(contrasts = c("contr.sum", "contr.poly"))
m <- lm(fm, data = d)
anova(m)

## Analysis of Variance Table
##
## Response: change
##          Df Sum Sq Mean Sq F value    Pr(>F)
## drug       1  888.0   888.0    40.075 9.36e-09
## center     4   87.1    21.8     0.983 0.420928
## drug:center 4  507.4    126.9     5.725 0.000376
## Residuals 90 1994.4     22.2
```

The `car` package allows to work with both Type II and Type III SS. Type III SSs, also called partial or Yates’ weighted squares of means are the default in Stata, SPSS or SAS. Stata does not even offer Type II SS. So, if we are interested in computing Type II sum of squares in R using `car`, we could call `Anova` like this:

```
car::Anova(m, type = "II")
```

```
## Anova Table (Type II tests)
##
## Response: change
##           Sum Sq Df F value    Pr(>F)
## drug       889.8  1  40.153 9.11e-09
## center     87.1  4   0.983 0.420928
## drug:center 507.4  4   5.725 0.000376
## Residuals 1994.4 90
```

Type III analysis is readily obtained by replacing `type = "II"` with `type = "III"` as shown in the next code block. It should be noted that without altering the default contrast treatment that are used by R, as we did in the above chunk, we would not get the correct results for the Type III analysis.

```
car::Anova(m, type = "III")
## Anova Table (Type III tests)
##
## Response: change
##           Sum Sq Df F value    Pr(>F)
## (Intercept) 22345  1 1008.344 < 2e-16
## drug         710  1   32.032 1.78e-07
## center       91  4    1.032 0.395313
## drug:center  507  4    5.725 0.000376
## Residuals   1994 90
```

Note that in the case of Type II SS, we can also use the base command `drop1` and we will get similar results:

```
drop1(m, scope = ~ ., test = "F")
## Single term deletions
##
## Model:
## change ~ drug * center
##           Df Sum of Sq  RSS   AIC F value    Pr(>F)
## <none>                 1994 319.3
## drug         1       709.8 2704 347.7  32.032 1.78e-07
## center       4        91.5 2086 315.8   1.032 0.395313
## drug:center  4       507.4 2502 334.0   5.725 0.000376
```

To sum up, the results from the different approaches are exposed in Table 2.

Remark. Here is how we could compute the parameter estimates and the SS corresponding to the drug effect in the case of a Type III analysis. The code follows what was posted on Stack Exchange, with minor adaptation. How this works is quite simple: We first get the design matrix stored in our model `m` and then solve the “normal equations” $(X'X)\hat{\beta} = X'y$ in order to get $\hat{\beta} = (X'X)^{-1}X'y$.

```
D <- model.matrix(m) ## design matrix
bhat <- solve(t(D) %*% D) %*% t(D) %*% d$change ## beta parameters
get.ss <- function(C) {
  require(MASS)
  teta <- C %*% bhat
  M <- C %*% ginv(t(D) %*% D) %*% t(C)
  SSH <- t(teta) %*% ginv(M) %*% teta
  return(as.numeric(SSH))
}
## SS(drug|center, drug:center)
get.ss(matrix(c(0,1,0,0,0,0,0,0,0,0), nrow = 1, ncol = 10))
## [1] 709.82
```

The authors later used the Gail-Simon test[Gail and Simon, 1985] to test for qualitative interaction

Table 2: Overview of fixed-effects analysis for the HAMD17 study

(a) Type I SS					(b) Type II SS					(c) Type III SS				
	Sum Sq	Df	F value	Pr(>F)		Sum Sq	Df	F value	Pr(>F)		Sum Sq	Df	F value	Pr(>F)
drug	888.04	1	40.07	0.0000	drug	889.78	1	40.15	0.0000	drug	709.82	1	32.03	0.0000
center	87.14	4	0.98	0.4209	center	87.14	4	0.98	0.4209	center	91.46	4	1.03	0.3953
drug:center	507.45	4	5.72	0.0004	drug:center	507.45	4	5.72	0.0004	drug:center	507.45	4	5.72	0.0004

```

This R package even provides a graphical method when specifying options `test = "IBGA"` and `plotout = TRUE` (Figure 3). The IBGA method relies on simultaneous 95% confidence intervals as described in Pan and Wolfe [1997]. The `multcomp` package also allows for simultaneous CIs albeit they are often used for testing multiple contrasts in ANOVA-like settings.

1.2 The Urinary incontinence trial

Context. This is a subset of data collected in an RCT on urinary incontinence where the primary endpoint was the percent change from baseline of number of incontinence episodes per week over an 8-week period. Patients were initially randomized into one of three strata depending on the baseline frequency of incontinence episodes.

This is an example of the use of stratified non-parametric analysis.

This time, we managed to get data in the right format using this little R script: `urininc.R`. Assuming it is located in an `R/` folder in the current working directory, we can source it into R and we will get a data frame named `d`.

Comparing Mean Differences

Figure 3: Average differences between drug and placebo stratified by centres

```
source("R/urininc.R")
str(d)

## 'data.frame': 200 obs. of 3 variables:
## $ group : Factor w/ 2 levels "Placebo","Drug": 1 1 1 1 1 1 1 1 1 ...
## $ strata: Factor w/ 3 levels "1","2","3": 1 1 1 1 1 1 1 1 1 ...
## $ change: num -86 -38 43 -100 289 0 -78 38 -80 -25 ...
```

To summarize the data, we can again make use of Hmisc summary for “crossed” data.

```
s <- summary(change ~ group + strata, data = d, method = "cross", overall = FALSE)
```

Table 3: Mean change in number of incontinence episodes by drug, strata

group	1			2			3		
	N	Missing		N	Missing		N	Missing	
Placebo	40	0	-29.0	32	8	-28.7	20	0	-11.7
Drug	39	1	-24.2	33	7	-53.8	19	1	-47.7

As can be seen, there is a higher number of missing values in strata 2 (around 20% in both groups) and larger variations on average between the two groups in the third strata. Next, we displayed the distribution of the percent change in frequency of incontinence episodes as density curves in Figure 4. Instead of relying on `geom_density`, we use the rather generic `geom_lines` with an extra `stat=` parameter.

```
p <- ggplot(data = d, aes(x = change, color = group)) +
  geom_line(stat = "density", adjust = 1.2) +
  facet_wrap(~ strata, ncol = 3) +
  scale_color_manual("Group", values = c("steelblue", "orange")) +
  scale_x_continuous(limits = c(-100, 150)) +
  labs(x = "Percent change", y = "Density")
p
```

The authors used the van Elteren test [van Elteren, 1960], which can be regarded as an extension of the Wilcoxon rank sum test for stratified data where larger weights are assigned to rank sums from

Figure 4: Density estimates for the percent change in frequency of incontinence episodes

smaller strata. An alternative is the “aligned rank test” proposed by Hodges and Lehman [1962] as discussed by Mehrotra et al. [2010]. In R, there is an old version that is mentioned on the R listserv (August 2005), but for now we will use the `coin` package as shown below:

```
library(coin)
dc <- subset(d, complete.cases(d))
independence_test(change ~ group | strata, data = dc,
                  ytrafo = function(data) trafo(data, numeric_trafo = rank,
                                                  block = dc$strata),
                  teststat = "quad")

##
## Asymptotic General Independence Test
##
## data: change by
## group (Placebo, Drug)
## stratified by strata
## chi-squared = 4.745, df = 1, p-value = 0.0294
```

Although we get different results as those reported by the authors, we would reach the same conclusion, namely that there is an effect of the treatment on the outcome after adjusting for the centre effect. We will get, however, closer results ($p = 0.02369$ for the row mean squares test statistic) if we simply remove the `scores=` option when calling SAS PROC FREQ [Stokes et al., 2012]:

```
PROC FREQ;
  TABLES strata*group*change / noprint cmh2;
RUN;
```

In comparison, as noted by the authors, a Type III ANOVA would yield non-significant result about the effect of drug on change scores:

```
m <- lm(change ~ group + strata, data = d)
car::Anova(m, type = "III")

## Anova Table (Type III tests)
##
## Response: change
##
##           Sum Sq Df F value Pr(>F)
## (Intercept) 176982  1 25.790 9.5e-07
## group         9602  1  1.399  0.238
## strata        8094  2  0.590  0.556
## Residuals  1228358 179
```

1.3 The Severe sepsis trial

Context. This is a placebo-controlled RCT examining the effect of an experimental drug on 28-day all-cause mortality in patients with severe sepsis. Patients were allocated to one of four strata depending on their APACHE II score [Knaus et al., 1985].

This is a classical application of stratified analysis of a binary outcome (dead/alive).

To enter the data in R, we will input individual values of the three-way Table of events as an array. Note that it would also be possible to create two matrix objects and then bind into to a 3-dimensional table. In what follows, we write data for the treated group first. Note that when using array, data should be entered column-wise (there is no `byrow =` option as in `matrix`).

```
varnames <- list(strata = 1:4,
                 status = c("Dead", "Alive", "Total"),
                 group = c("Experimental", "Placebo"))
d <- array(c(33,49,48,80,185,169,156,130,218,218,204,210,
            26,57,58,118,189,165,104,123,215,222,162,241),
          dim = c(4,3,2), dimnames = varnames)
```

Note also that the third column ("Total") can be safely omitted as margins can be computed automatically with R, e.g.:

```
addmargins(d[, -3, ], c(1,2))
```

```
d <- d[, -3, ]
dim(d)
## [1] 4 2 2
```

An alternative representation of this array-based Table is provided by R's flat tables (`ftable`), in long or wide format; see Table 4 for the wide format using `ftable(d, row.vars = 1, col.vars = c(3,2))`:

```
ftable(d)
##           group Experimental Placebo
## strata status
## 1      Dead           33        26
##       Alive          185       189
## 2      Dead           49         57
##       Alive          169       165
## 3      Dead           48         58
##       Alive          156       104
## 4      Dead           80        118
##       Alive          130       123
```

strata	group:	Experimental		Placebo	
	status:	Dead	Alive	Dead	Alive
1		33	185	26	189
2		49	169	57	165
3		48	156	58	104
4		80	130	118	123

Table 4: 28-day mortality data from the 1690-patient sepsis study

The following code is used to depict the situation in graphical terms:

```
library(plyr)
dd <- as.data.frame(ftable(d))
r <- ddply(dd, c("strata", "group"), mutate, prop = Freq/sum(Freq))
p <- ggplot(subset(r, status == "Dead"), aes(x = prop, y = group)) +
```

Figure 5: Proportion of patients who died by the end of the study

```
geom_point() + facet_wrap(~ strata, nrow = 2) +
scale_x_continuous(limits = c(0,0.5)) +
labs(x = "Proportion deads", y = "")
```

p

```
library(vcd)
cotabplot(d, 1)
```

Based on a logistic regression model, the authors presented a summary of a Type III analysis of effects. Here is what can be done in R. First, we will slightly re arrange the data table so that we have a working data frame with total counts for successes (here, dead patients) and failure (patients still alive) in separate columns, together with columns describing strata and treatment levels.

```
n <- rbind(d[,1:2,1], d[,1:2,2])
rownames(n) <- NULL
n <- as.data.frame(n)
n$strata <- gl(4, 1)
n$group <- gl(2, 4, labels = c("Experimental", "Placebo"))
n$group <- relevel(n$group, ref = "Placebo")
```

Then, since we are working with grouped or aggregated data, we will use the `cbind()` option in R's `glm` function, as shown below. Note that we also ask to use SAS treatment contrast for the strata factor, in order to ensure that the fourth level is used as the reference category. Type III analysis is readily available within the `car` package.

```
m <- glm(cbind(Dead,Alive) ~ group + strata, data = n, family = binomial,
         contrasts = list(strata = "contr.SAS"))
car::Anova(m, type = "III")

## Analysis of Deviance Table (Type III tests)
##
## Response: cbind(Dead, Alive)
##      LR Chisq Df Pr(>Chisq)
## group      6.99  1    0.0082
## strata    105.61  3    <2e-16
```

Finally, profile likelihood 95% confidence intervals are simply obtained using `confint()` which will

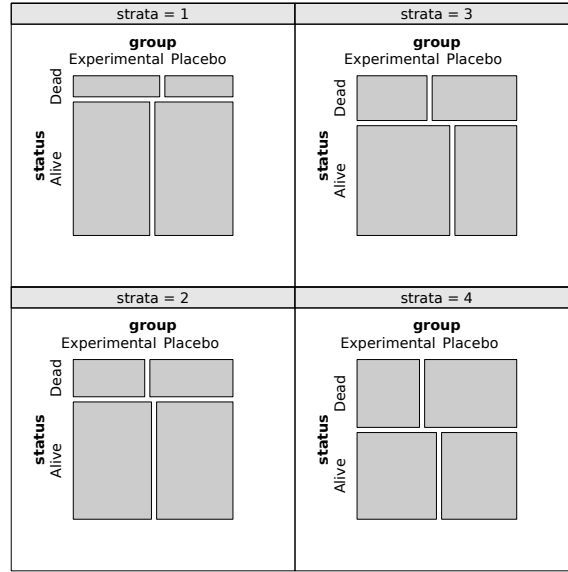

Figure 6: Conditional association plot

call the appropriate profile method depending on the kind of model at hand:

```
exp(confint(m))

##              2.5 %    97.5 %
## (Intercept) 0.641248 0.931819
## group1      1.039214 1.296530
## strata1     0.144325 0.280712

1.4 The dose-finding hypertension trial

Context. This trial aimed to compare low, medium and high doses of a new antihypertensive drug to a placebo. The primary efficacy variable that is being considered in this study is diastolic blood pressure.

This example is used to illustrate various methods to deal with multiple testing issues. In what follows we will work with p-values (raw data are not available) estimated when comparing all four groups (P, placebo vs. L, M, and H, the low, medium and high dose groups).

	L vs. P	M vs. P	H vs. P
Scenario 1	0.047	0.0167	0.015
Scenario 2	0.047	0.027	0.015
Scenario 3	0.053	0.026	0.017

Table 5: P-values obtained from different approaches

The `p.adjust()` command can be used to compute various “adjusted” p-values, the default being the step-down method proposed by Holm [1979].

```
pvals <- c(0.047, 0.0167, 0.015) ## scenario 1
p.adjust(pvals, method = "bonferroni")

## [1] 0.1410 0.0501 0.0450
```

The Šidák method is not available in `p.adjust()` but it is not difficult to implement a custom function to perform this correction which amounts to update the nominal α level with $1 - (1 - \alpha)^{1/n}$,

that is:

```
f <- function(x) (1-(1-x)^length(x))
f(pvals)
## [1] 0.1344768 0.0492680 0.0443284
```

Alternatively, one can dig into the `multtest` package by Dudoit and van der Laan [2008], available on <http://www.bioconductor.org> (see the `mt.rawp2adjp()` command).

Contrary to the preceding results, Holm's adjusted p-values will all be < 0.05 as illustrated below:

```
p.adjust(pvals, method = "holm")
## [1] 0.047 0.045 0.045
```

And here is a comparison of Holm and Hommel's adjusted p-values for the second scenario (Table 5):

```
pvals <- c(0.047, 0.027, 0.015) ## scenario 2
p.adjust(pvals, method = "holm")
## [1] 0.054 0.054 0.045
p.adjust(pvals, method = "hommel")
## [1] 0.0470 0.0470 0.0405
```

Finally, Hommel's method is compared to Hochberg's approach for the third scenario:

```
pvals <- c(0.053, 0.026, 0.017) ## scenario 3
p.adjust(pvals, method = "hochberg")
## [1] 0.053 0.052 0.051
p.adjust(pvals, method = "hommel")
## [1] 0.053 0.052 0.039
```

One can also look into the `cherry` package [Goeman and Solari, 2011] whose vignette includes a comparison of Simes vs. Hommel or Fisher approach to multiple testing, as well as examples of closed testing methods.

1.5 The allergen-induced asthma trial

Context. Data comes from a trial designed to assess the efficacy profile of a bronchodilator in allergen-induced asthma. There are 20 patients that were randomly assigned to receive either an experimental drug or a placebo [Taylor et al., 1991]. The forced expiratory volume in one second (FEV) was used to measure how the drug attenuated bronchoconstriction, and FEV curves were averaged at each time point in both groups (Table 6). The therapeutic effect was the time to the onset of action—that is, the first time point at which clinically and statistically significant separation between the FEV curves is observed.

Beside stepwise approaches relying on data-driven ordering of p-values—this is also known as closed testing—fixed-sequence testing methods are used when we are interested in prespecified sequences of hypotheses. This is illustrated in the next example.

To load the data, we will use a simple matrix to store the values displayed in Table 6 and then reshape the matrix to a so-called “tidy” data frame using `melt`, although this last step is not really necessary.

```
tmp <- matrix(c(0.25,10,0.58,0.29,10,0.71,0.35,
               0.5,10,0.62,0.31,10,0.88,0.33,
               0.75,10,0.51,0.33,10,0.73,0.36,
               1,10,0.34,0.27,10,0.68,0.29,
               2,10,-0.06,0.22,10,0.37,0.25,
```

	Experimental drug			Placebo		
Time (hours)	n	Mean	SD	n	Mean	SD
0.25	10	0.58	0.29	10	0.71	0.35
0.5	10	0.62	0.31	10	0.88	0.33
0.75	10	0.51	0.33	10	0.73	0.36
1	10	0.34	0.27	10	0.68	0.29
2	10	-0.06	0.22	10	0.37	0.25
3	10	0.05	0.23	10	0.43	0.28

Table 6: Reduction in FEV measurements from baseline by time after the allergen challenge

Figure 7: Treatment comparisons in the asthma study

```

3,10,0.05,0.23,10,0.43,0.28),
nrow = 6, byrow = TRUE)
colnames(tmp) <- c("time", "N0", "Mean0", "SD0", "N1", "Mean1", "SD1")
d <- melt(as.data.frame(tmp), id.vars = 1, measure.vars = c(3,4,6,7))

```

Note that it is quite easy to go back to the matrix form by using `dcast` as shown below:

```

r <- ddply(dcast(d, time ~ variable), "time", mutate,
diff = Mean1 - Mean0, se = sqrt((1/10+1/10)*(SD0^2+SD1^2)/2))

```

In what follows, we compute the lowest bound of a 95% confidence interval and display its value at consecutive time points. This amounts to looking at results from sequential testing, i.e. determine the first statistically significant difference. Equivalently, we could rely on simple Student t-test.

```

p <- ggplot(r, aes(x = time, y = diff))
p <- p + geom_line() + geom_point()
p <- p + geom_line(aes(x = time, y = diff - qt(0.95, 20-2) * se), linetype = 2)
p <- p + scale_x_continuous(breaks = seq(0, 3, by = 1))
p <- p + scale_y_continuous(breaks = seq(-0.2, 0.5, by = 0.1))
p <- p + geom_hline(aes(yintercept = 0))
p + labs(x = "Time (hours)", y = "Treatment difference (95% Lower CI)")

```

Note that to display error bars instead of the lower bound for the 95% confidence interval, we would

use:

```
p <- p + geom_errorbar(aes(ymin = diff - qt(0.975, 20-2) * se,  
                           ymax = diff + qt(0.975, 20-2) * se),  
                       width = .1)
```

This approach, however, does not control the familywise error rate. Looking at treatment differences from the last measurement to the first (“step-down” approach) suggests that a significant difference at one hour, and not 30 minutes as in the previous case.
